July 2015

Abstract

We study how the composition of capital imports affects relative demand for skill and the skill premium in a sample of developing economies. Capital imports per se do not affect the skill premium; in contrast, their composition does. While imports of R&D-intensive capital equipment raise the skill premium, imports of less innovative equipment lower it. We estimate that R&D-intensive capital is complementary to skilled workers, whereas less innovative capital equipment is complementary to unskilled labor—which explains the composition effect. This mechanism has substantial explanatory power. Variation in tariffs, freight costs and overall barriers to trade, over time and across types of capital, favors imports of skill-complementary capital over other types. We calculate that reductions in barriers to trade increase inequality substantially in developing countries through the composition channel.

JEL classifications: F14, F16, J23, J24, J31, O10, O30

Keywords: Capital imports; capital-skill complementarity; skill premium; trade liberalization

We also thank seminar participants at Bar-Ilan University, Ben-Gurion University, Haifa University, Hebrew University of Jerusalem, IDC-Herzliya, Queens College CUNY, Tel-Aviv University, UC Davis, University of Oxford, University of Zurich, the 2013 Econometric Society European Winter Meetings, the 2013 Empirical Investigations in International Trade Conference, and the 10th Annual Conference on Economic Growth and Development, for helpful discussions. Raveh gratefully acknowledges financial support from the Social Sciences and Humanities Research Council of Canada.
1 Introduction

The concurrent rise in trade flows and increase in the skill premium in several developing countries is one of the most striking economic phenomena of the 1980s and 1990s (Goldberg and Pavcnik (2007)), and has prompted many economists to ask: Is there a causal relationship between the two? And if so, what is the mechanism? The failure of standard Heckscher-Ohlin theory to explain distributional changes across skill groups in developing countries has shifted focus to more nuanced forms of competition in the final goods space, or to other channels through which globalization may affect factor prices.\footnote{1 See Feenstra and Hanson (1996), Zhu and Trefler (2005), Yeaple (2005), Zeira (2007), Verhoogen (2008), Bustos (2011), Burstein and Vogel (2012), Harrigan and Reshef (2012) and Bonfatti and Ghatak (2013). Harrison, McLaren, and McMillan (2011) provide a recent survey.} \footnote{2 The failure to detect Stolper-Samuelson effects in skill abundant countries, let alone in unskilled abundant countries, together with scant evidence of industry reallocations due to trade liberalization, have prompted many researchers to abandon the trade explanation altogether and focus on technological explanations, for example Berman, Bound, and Griliches (1994) and Machin and Van Reenen (1998). However, see also Bernard and Jensen (1997) for evidence on the importance of trade-induced changes in demand for skill and reallocations across plants within industries.}

In this paper we empirically study a new channel: Variation in the composition of capital equipment imports. While other papers highlight the role of capital imports under the assumption of capital-skill complementarity (Griliches (1969)) within structural quantitative trade models (Burstein, Cravino, and Vogel (2013), Parro (2013)), this paper is the first to test the mechanism directly, in a sample of developing countries. We find that capital imports \textit{per se} do not affect the skill premium; rather, it is the \textit{composition} of capital imports that matters. While imports of R&D-intensive capital equipment raise the skill premium, imports of less innovative capital equipment actually lower the skill premium.

As Figure 1 illustrates, a high ratio of R&D-intensive capital relative to less innovative capital imports (henceforth, the capital import ratio) is associated with larger increases in the skill premium, while the overall level of capital imports does not matter (as we illustrate below). A shift in the composition of imports towards R&D-intensive capital shifts the composition of investment in developing countries, and hence the composition of the capital stock towards more skill-complementary capital, and increases demand for skill. The explanatory power of this mechanism in our sample of developing countries is economically large: An increase in the capital import ratio from first to third quartile increases the change in the skill premium by two-thirds of the corresponding inter-quartile change, all else equal. This is the first contribution of this paper. We then investigate why this is the case.

We find that only R&D-intensive capital equipment is complementary to skilled labor; in con-
contrast, we find that less innovative capital equipment is complementary to unskilled labor. To our best knowledge, we are the first to empirically document that some types of capital are more complementary to unskilled workers. Acemoglu (2002) suggests an explanation for why this is the case: An increase in the supply of skilled labor in industrial economies, which occurred during the same period that we study, "directs" more innovation and resources (read: R&D expenditures) towards developing skill-complementary machines, and relatively less towards machines that are complementary to unskilled workers (the "market size effect").

In the model of Acemoglu (2003) technology firms in less developed countries copy blueprints of machines from developed countries (at some cost), produce them domestically, and sell to final goods producers. If the ability to successfully copy is not available or is not optimal, then importing machines from developed countries is another way to obtain the technology that they embody. Our work focuses on this channel of embodied technology diffusion. Indeed, developing countries import much of their equipment, which originates mostly in developed, skill abundant countries (Eaton and Kortum (2001)); therefore, we can treat capital imports as a good measure of investment in developing countries (Caselli and Wilson (2004)). We present detailed evidence that supports this argument. Therefore, it is reasonable to infer the characteristics of capital investment in developing economies based on data from developed economies.

Finally, we ask whether trade liberalization generally increases the skill premium. The capital composition mechanism described above only tells us how trade liberalization may increase the skill premium. In this context, the question is whether trade liberalization shifts the distribution of capital imports towards more skill-complementary equipment. We provide evidence that is consistent with this.

We show that tariffs and freight costs dropped more for skill-complementary capital imports than for unskilled-complementary capital imports. We also show that bilateral trade resistance fell differentially for skilled-complementary equipment relative to unskilled-complementary capital imports—both for our sample of developing countries and more generally. The increase in the import ratio through this mechanism alone increases the change in the relative wage of skilled workers in our sample of developing countries by $1 - 1.2\%$ per year, which is about one third of the inter-quartile change.

This paper contributes to three broad strands of literature: Trade liberalization and changes in relative demand for skill; capital-skill complementarity; and the effect of computers on relative demand for skill.

---

3 Similar ideas are investigated in Galor and Moav (2000), but the framework in Acemoglu (2002) is more closely related to ours. Both are reminiscent of historical accounts of innovation and demand for skill in Goldin and Katz (2008).
First, we provide empirical evidence for a new mechanism that links trade liberalization and relative factor demand in developing countries—through the composition of capital imports. Caselli and Wilson (2004) document broad cross-country variation in the composition of capital imports by R&D intensity. They link this composition to differences in total factor productivity. Coe and Helpman (1995) and Acharya and Keller (2009) investigate the role of aggregate imports in facilitating R&D spillovers and technology transfers. None of these studies address changes in relative demand for skill and distributional consequences. Burstein, Cravino, and Vogel (2013) and Parro (2013) assume that aggregate capital is complementary to skill, but do not test whether this is indeed the case, nor do they allow for different types of capital with different complementarities.

Our work is also related to Koren and Csillag (2012), who show how imports of machines increase the wages of workers whose occupations are particularly complementary to those machines. While their estimates focus on micro, within-worker effects in Hungary alone, we address relative demand shifts for the entire economy, in 21 developing countries. Zhu and Treffer (2005) offer an elegant general equilibrium model and show how trade liberalization may increase demand for skill in developing countries through shifts in the composition of exports towards skill intensive goods. We exploit similar data in our analysis, and find that our mechanism is independent of theirs. We also demonstrate that the capital imports composition is a much stronger mechanism for affecting the skill premium.

We highlight the effects of trade liberalization through the input side of production. For example, Amiti and Konings (2007) study how greater access to inputs increases productivity, and Goldberg, Khandelwal, Pavcnik, and Topalova (2010) show how this may have an effect on growth in the number of products produced. Amiti and Davis (2012) find that trade liberalization increases average wages at firms that import more intermediate inputs in Indonesia, and offer a fair-wage mechanism to explain their findings. However, all these papers do not investigate distributional effects. Our work can help explain results in Amiti and Cameron (2012), who find that imports of intermediate inputs tend to lower skill premia within firms in Indonesia.\(^4\) Amiti and Cameron (2012) do not study complementarities of intermediate inputs with skilled and unskilled labor, and their results are confined to firms that actually import. While our results pertain to the entire economy, we conjecture that similar forces (composition of imported intermediate inputs in conjunction with complementarities) drive their results. Saravia and Voigtländer (2012) argue that high quality intermediate inputs substitute for skilled workers, but that the quality gains at the firm output level increase returns to employing skilled workers. In contrast to all these studies, we focus on aggregate, economy-wide relative demand effects that are not confined to importing firms.

\(^4\)Indonesia is not one of the countries in our sample.
alone. Thus, while our approach is less forensic in nature, we capture broader implications.

The second strand of literature to which we contribute studies capital-skill complementarity. Since the seminal work of Griliches (1969) it has become standard to assume that capital is complementary to skilled labor. Several studies adopt this framework in order to address questions on economic growth, trade, and inequality.\(^5\) This body of work uses aggregate measures of capital; in contrast, we show that complementarities vary systematically at disaggregated levels. Our analysis reveals that it is the most innovative, R&D-intensive capital that is complementary to skilled workers, while other types of capital are in fact complementary to the unskilled. These results are robust to different definitions of skill. This can help explain the lack of robustness in previous attempts to test the aggregate capital-skill complementarity hypothesis, e.g. Duffy, Papageorgiou, and Perez-Sebastian (2004): Differences in the composition of capital across countries and over time may render the overall characterization of complementarity elusive.

Finally, our work is also related to the literature on computers and demand for skill. We find that the R&D-intensive, skill-complementary capital is, to a first approximation, mostly composed of information and communications technology (ICT) equipment. The work of Autor, Katz, and Krueger (1998), Bresnahan, Brynjolfsson, and Hitt (1999), and Autor, Levy, and Murnane (2003) all indicate that this type of equipment raises relative demand for skilled labor, although their empirical results focus on the U.S. Michaels, Natraj, and Van Reenen (2011) study the effect of ICT capital deepening on polarization of labor demand in developed countries. They find that ICT deepening reduces relative demand for medium-skilled workers, while increasing relative demand for high skill workers.\(^6\) While we take advantage of similar distinctions between types of capital in some of our specifications, we investigate in greater detail the pattern of complementarities across more disaggregate types of capital, relate this pattern to R&D intensity, and find that other types of capital are actually complementary to unskilled labor—a new result. In addition, we apply our results to imports in developing countries.

After introducing the framework that underpins our analysis in Section 2, in Section 3 we document the strong effect of the composition of capital imports on the skill premium. In Section 4 we show that more R&D-intensive capital equipment is complementary to skilled labor, and that less innovative capital equipment is complementary to unskilled labor. Section 5 argues that trade liberalization increases inequality through the composition channel. Section 6 concludes.

2 Analytical framework

In this section we lay out a simple analytical framework to help organize the discussion. Since we are considering developing countries, we ignore the possibility to produce capital goods domestically, but allow them to import capital goods, whose prices are given internationally. We make an Armington assumption and let final goods be differentiated by country of production. We ignore balanced trade considerations, since these are not essential to the analysis here.

There are two types of capital—\( C \) and \( K \) (think computers and tractors, respectively)—and two types of labor—skilled \( H \) and unskilled \( L \). The aggregate production function for the economy is

\[
Q = \left[ \delta X^{\frac{\sigma-1}{\sigma}} + (1 - \delta) Y^{\frac{\sigma-1}{\sigma}} \right]^{\frac{\sigma}{\sigma-1}},
\]

where

\[
X = H^\beta C^{1-\beta},
\]

\[
Y = L^\beta K^{1-\beta},
\]

\( \beta \in (0,1) \) and \( \sigma > 1 \). The only critical assumption here is that each type of capital is more complementary to one type of labor than with the other: \( C \) with \( H \)—and \( K \) with \( L \). Any production function that maintains this property will suffice. We devote Section 4 to justifying this assumption. Although not a necessary assumption, this production function exhibits the same degree of complementarity between \( C \) and \( H \) as between \( K \) and \( L \), and equal expenditure shares. Allowing elasticities and \( \beta \)’s to vary across \( X \) and \( Y \) complicates the discussion without providing additional insight. In fact, our estimates in Section 3 and in Section 4 are broadly consistent with this symmetry.\(^7\) Estimates of the aggregate elasticity of substitution between \( H \) and \( L \) in the literature are typically above unity; this implies \( \sigma > 1 \).\(^8\)

Workers supply labor—both \( H \) or \( L \)—inelastically. Denote the wage of skilled labor by \( w_H \) and the wage of unskilled labor by \( w_L \). Denote the price of capital as \( r_j \) for \( j \in \{C,K\} \). Competitive factor markets imply that factors are paid the value of their marginal product.\(^9\)

\(^7\) In Tables 6 and 7 the coefficients to skill-complementary and unskilled-complementary capital equipment are very similar in absolute value, with some tendency towards \( Y \). Applying the latter point to the model further supports the proposed mechanism, making this a simplifying feature. Acemoglu (2002) also makes this assumption to streamline his model.

\(^8\) The elasticity of substitution between between \( H \) and \( L \) in the current framework is \( \sigma/[\sigma - \beta(\sigma - 1)] \). If this is greater than unity, then so is \( \sigma \), given \( \beta \in (0,1) \). For the U.S., Katz and Murphy (1992) estimate an aggregate elasticity of substitution between college and high-school graduates at 1.4. More recent estimates are reported by Heckman, Lochner, and Taber (1998) at 1.44, and Krusell, Ohanian, Rios-Rull, and Violante (2000) at 1.67. Despite estimating an elasticity of substitution in services at less than one, Reshef (2013) estimates an aggregate elasticity (that takes into account substitution across sectors, not just within) above one.

\(^9\) The model is static, so we ignore capital depreciation. This does not affect our empirical analysis, unless de-
Some algebra (see appendix) yields

$$
\omega = \frac{\delta}{1 - \delta} \left( \frac{H}{L} \right)^{-\frac{\sigma - \beta (\sigma - 1)}{\sigma}} \left( \frac{C}{K} \right)^{\frac{(1-\beta)(\sigma-1)}{\sigma}},
$$

(1)

where $\omega \equiv w_H/w_L$. Holding constant $C/K$, greater skill abundance $H/L$ reduces the relative wage of skilled labor $\omega$. Holding constant $H/L$, a greater $C/K$ ratio also increases $\omega$ as long as $\sigma > 1$.\(^{10}\)

Equation (1) also shows that the overall quantity of capital $C + K$ is not important for determining $\omega$: Only the composition matters.

Taking logs of (1) we have

$$
\ln \omega = \kappa - \alpha \ln \left( \frac{H}{L} \right) + \lambda \ln \left( \frac{C}{K} \right),
$$

(2)

where $\kappa = \ln \left[ \frac{\delta}{(1 - \delta)} \right]$, $\alpha = 1 - \beta (\sigma - 1)/\sigma$, and $\lambda = (1 - \beta) (\sigma - 1)/\sigma$. Taking differences of (2) yields

$$
\Delta \ln \omega = -\alpha \Delta \ln \left( \frac{H}{L} \right) + \lambda \Delta \ln \left( \frac{C}{K} \right).
$$

(3)

In the empirical counterpart to (3) we include country fixed effects (e.g., due to variation in changes in industrial structure $\delta$) and other controls. We also include time effects to deal with common unobserved trends (e.g., disembodied technological change).

Before turning to the empirical analysis we make the following observation. An alternative interpretation of $Q$ is utility over a skill intensive good $X$ and a skill un-intensive good $Y$. This would open the door to production and export composition effects that are reminiscent of Zhu and Trefler (2005) (henceforth, ZT)—but for different reasons and through a different mechanism. We shut down this channel in our framework because our analysis leads us to believe that the mechanism highlighted in ZT is not tightly related to ours. There are two reasons for this.

First, using data from EU-KLEMS (O’Mahony and Timmer (2009)), we find that changes in empirical counterparts of $C$ and $K$ contribute little to changes in relative demand for skill via changes in industrial composition alone, net of within-industry changes in skill intensity. This is done by multiplying the contribution of each type of capital to different industries’ overall growth times industry skill intensity, and aggregating using industry weights in the beginning of the sample (see details in the appendix and in Table A2). Moreover, it seems that $K$ contributes just as much

precision rates vary systematically across countries and over time with changes in relative wages, which is unlikely. In the empirical implementation we control for time fixed effects, which absorb, inter alia, common time-varying depreciation.

\(^{10}\)When $\sigma < 1$ strong complementarity between $X$ and $Y$ change the direction of the effect. Take the extreme case of $\sigma = 0$, i.e. fixed proportions in $X$ and $Y$. An increase in $C/K$ increases the relative supply of $X/Y$, but since there is no substitution we do not need as much $X$ and hence demand for skilled labor falls.
to increases in skill intensity through the industry composition channel as \( C \) does.\(^\text{11}\) Second, the changes in export shares towards skill intensive goods in ZT (their \( \Delta z \)) are negatively correlated with the composition of capital imports (see Table A1). If an increase in demand for skilled labor is reflected in a shift in the composition of exports, then the correlation should have been in the opposite direction. This may not be surprising, since ZT examine only changes in manufacturing export shares, while capital imports can affect the entire economy, not only the tradable sector. In the empirical implementation we control for \( \Delta z \) in all specifications.

3 Capital imports and the skill premium: 1983–2000

In this section we demonstrate that the composition of capital imports explains changes in skill premia in developing countries, whereas overall capital imports do not. We focus on the 1980s and 1990s, during which many developing countries—and specifically the ones in our sample—liberalized their international trade regimes.\(^\text{12}\)

3.1 Data

Since we do not have empirical equivalents for \( C \) and \( K \) for developing countries, we rely on imports of capital to approximate changes in capital stocks, i.e. investment. This is a reasonable assumption for the developing countries in our sample, since they import most of their capital during our period of interest. We document this fact in detail in Section 3.2 below, as well as the tight correlation between imports and "implied investment" (defined below).

All trade data are from Feenstra, Lipsey, Deng, Ma, and Mo (2005). We break down total capital imports (\( M \)) into imports of R&D-intensive capital (\( M_H \)), and imports of relatively R&D-unintensive capital (\( M_L \)). Capital goods are defined as ISIC rev.2 category 38, "Manufacture of Fabricated Metal Products, Machinery and Equipment". R&D intensity ranking of capital goods in 1980 is taken from Caselli and Wilson (2004) and are briefly described in Table 1. Their ranking of nine types of equipment is based on estimates of world R&D expenditures divided by world sales for each capital good; it is the same whether R&D flows or stocks (perpetual inventory method)

\(^{11}\)It is not surprising that non-ICT capital contributes just as much as ICT capital through this channel, since non-ICT capital is a much larger share of capital stocks. Berman, Bound, and Griliches (1994) calculate that only 30% of the skill intensity increase in U.S. manufacturing in the 1980s is due to changes in industry composition. Our calculation is consistent with this.

\(^{12}\)For instance, data from the World Bank’s World Development Indicators (available at: http://data.worldbank.org/data-catalog/world-development-indicators) reveal that the average increase between 1980-1999 in the share of total trade in GDP for all countries in our sample is approximately 40%, having several countries more than doubling their trade share during this period, including Argentina, India, Mexico, Thailand, and the Philippines. Goldberg and Pavcnik (2007) provide evidence on trade-liberalizing policy changes during our period of interest in some of the countries in our sample, including Argentina, Mexico, India, and Hong Kong.
are used. $M_H$ includes five of the most R&D-intensive capital equipment, while $M_L$ includes the remainder least R&D-intensive capital equipment. This division is based on the estimated complementarity levels to skilled and unskilled labor, as demonstrated in Section 4 below. Our empirical equivalents of $C$ and $K$ are R&D-intensive and R&D-unintensive capital, respectively.

We merge import data with data on changes in relative skilled wages. We follow and extend Zhu and Trefler (2005) methodology, encompassing the most comprehensive sample of developing countries for which there are data on relative skilled wages in the time sample of interest. These are based on the availability of wages for non-production (skilled) and production workers in manufacturing from the International Labor Organization’s occupational wage database. In addition to using a maximized sample, this has the advantage of direct comparability to ZT’s results, with the difference of adding Hungary to the sample (for which data was previously unavailable). The sample includes 63 observations covering 21 developing countries in 1983–2000, and is an unbalanced panel due to data availability.\(^\text{13}\) Although the sample is relatively small, this is the best data and most relevant sample. Despite the small sample size, the estimates are precise and robust.

We use the relative wage of non-production to production workers as our measure of skilled relative wages $\omega = w_H/w_L$.\(^\text{14}\) We compute the shift towards more skill-intensive exports within a given period $\Delta z$, exactly as described in Zhu and Trefler (2005).\(^\text{15}\) ZT argue that $\Delta z$ can help explain changes in wage inequality; we examine below the relative importance of ZT’s mechanism versus capital imports composition. Our measure of aggregate relative supply of skilled labor (skill abundance) $(H/L)$ uses data from Barro and Lee (2013). Skilled workers $H$ have at least secondary education and unskilled workers $L$ have less than that level of education. Educational attainment data are available every 5 years, so we linearly interpolate between observations within a country.

We use the following ancillary control variables. From the World Bank’s World Development Indicators: Government, services and industrial shares in value added; a measure of financial development (M3/GDP); GDP and population. We use data on foreign direct investment (FDI) position of U.S. multinational firms in the countries in our sample from the Bureau of Economic Analysis. We use the intellectual property rights protection index (IPR) from Ginarte and Park

\(^{13}\) The criterion for being considered a developing country is having real GDP per capita below $14,000 in 1980. The countries in the sample are: Algeria, Argentina, Barbados, Bolivia, Central African Republic, Cyprus, Honduras, Hungary, Hong Kong, India, South Korea, Sri Lanka, Madagascar, Mauritius, Mexico, Philippines, Singapore, Thailand, Trinidad and Tobago, Uruguay, and Venezuela. See the appendix for the years in which each country is observed.

\(^{14}\) Proxying skill by "non-production" is problematic, though it is common practice by necessity. Berman, Bound, and Griliches (1994) show that for the United States, the production/non-production worker classification is a good proxy for skilled and unskilled workers. In our estimation of complementarities below we entertain other definitions of skill.

\(^{15}\) See appendix for details on the construction of $\Delta z$, which we extended (following ZT’s methodology) to 2000.
(1997), updated by Park (2008); these data are available every 5 years, so we linearly interpolate between observations within a country. Finally, we use the total capital stock data from Penn World Tables, mark 8.0.\(^\text{16}\)

Table 2 reports descriptive statistics for the main variables of interest. During the sample (a period of trade liberalization) the relative wage of skilled worker increased for half of the countries, while the other half experience decreasing relative wage; overall, changes in \(w_H/w_L\) are roughly split between positive and negative changes. The log of the import ratio \(M_H/M_L\) is on average \(-0.012\), which implies that R&D-intensive capital imports are approximately equivalent in value relative to R&D-unintensive capital imports \((e^{-0.012} \approx 0.99)\).

Importantly, we find a relatively weak and statistically insignificant correlation between \(\Delta \ln (H/L)\) and \(\ln (M_H/M_L)\). This is important because, as we discuss below in more detail, the potential endogeneity of \(\Delta \ln (H/L)\) does not bias the estimator of the coefficient to \(\ln (M_H/M_L)\). In other words, it is reasonable to assume conditional mean independence for \(\ln (M_H/M_L)\) with respect to \(\Delta \ln (H/L)\).

\[3.2 \text{ Imports and investment}\]

In this section we make two important points: First, that capital imports account for most of the investment in the sample of countries that we examine; and second, that capital imports are strongly correlated with investment. Before doing so, we describe the distribution of capital imports and changes thereof.

Table 3, Panel A reports the distribution of capital imports. The sample is restricted to the unbalanced panel that is described above and in greater detail in the appendix. There is substantial variation in these shares across countries in our sample. On average, the shares of \(M_H\), and \(M_L\) are 48.4\%, and and 51.6\%, respectively. Panel B documents substantial variation across countries in the changes in these shares. On average, the share of \(M_H\) increases by 0.5 percent points \(\text{per year}\), offset by a commensurate decrease in the share of \(M_L\); capital imports become more R&D intensive and more skill-complementary over time. Over the period 1983–2000 there is a shift of 8.5 percent points towards \(M_H\).

We now assess the importance of capital imports in "implied investment", which we define as domestic absorption of capital equipment

\[I = Y + M - X ,\]

\(^{16}\)Penn World Tables, mark 8.0 is available at the University of Groningen, http://citaotest01.housing.rug.nl/febpwt/Home.mvc.
where $Y$ is output, $M$ are imports and $X$ are exports. Output data on capital equipment are from UNIDO (2013), and are available at the 2-digit ISIC Rev.3 classification. The 2-digit classification allows aggregating up to the two main groups that are also used for imports and exports. The only mismatch is for aircraft equipment, which cannot be separated from "other transport equipment", and is allocated to $Y_L$. The main limitation of the UNIDO data is that country and year coverage are sparse for our sample. Another limitation is that part of "implied investment" of capital goods may be, in fact, absorbed by households as durable goods. Nevertheless, the data are informative. We match import data to output data for all possible observations.

Table 4 reports the share of imports in implied investment, $M/I$. On average, $M_H$ and $M_L$ are 83% and 64% of $H$-type and $L$-type investments respectively, with the notable outliers of Korea and India (which produce and export much of this equipment). Overall, imports are 72% of investment. We also report shares of net imports ($N = M - X$) in investment. Net imports can help offset the effect of importing intermediate inputs that are assembled and then exported, when both flows fall within the same classification. The shares of net imports in investment are necessarily lower (especially for Mexico, due to the maquiladora sector), but they are still substantial, especially for $H$-type investment.

Next, we turn to the correlation of imports with implied investment. Table 5 reports pairwise correlation coefficients between the two types of implied investment and capital imports or net imports, of the respective kind. In addition, the table reports correlations of total investment with total capital imports or net imports. By and large, imports and net imports are highly correlated with investment. The exceptions occur for countries that are big exporters of capital of a particular type, where net imports are negatively correlated with investment. This is a consequence of output being strongly correlated with exporting for these cases. For example, Korea is a big exporter of all capital types; India exports $L$-type, but not $H$-type capital. The regression results in the next two sections are robust to the exclusion of these countries.

Overall, the evidence implies that capital imports are a good approximation for investment. It is likely to be particularly good for $H$-type investment, since developing countries rely much more on imports of R&D-intensive capital, relative to R&D-unintensive capital.

---

17 The relevant 2-digit ISIC Rev.3 categories are: 28 Fabricated metal products, 29 Machinery and equipment n.e.c., 30 Office, accounting and computing machinery, 31 Electrical machinery and apparatus, 32 Radio, television and communication equipment, 33 Medical, precision and optical instruments, 34 Motor vehicles, trailers, semi-trailers, 35 Other transport equipment. $Y_H$ includes $30 + 32 + 33 + 34$, and $Y_L$ includes $28 + 29 + 31 + 35$.

18 For example, "Office, Accounting and Computing Machinery" (ISIC 3825) may include computers for personal use; "Motor vehicles" (ISIC 3843) may include cars for personal use.
3.3 Capital imports and the skill premium: OLS estimates

We now turn to testing our main hypothesis. Equation (3) implies a relationship between changes in relative skilled wages \( \omega = w_H/w_L \) and changes in the ratio of skill-complementary to unskilled-complementary capital \((C/K)\), but not with overall levels of capital \((C + K)\). We approximate changes in \(C/K\) with the import ratio. Changes in \(\ln (C/K)\) do not map precisely into \(\ln (M_H/M_L)\). Therefore, we experiment with several specifications: We use each type of capital imports as a ratio to GDP, to population and to the total capital stock, or simply in logs. We also estimate specification not in logs. The results are not sensitive to these changes and are reported in the appendix.

We estimate the empirical counterpart to equation (3),

\[
\Delta \ln \omega_{it} = \lambda \ln \left( \frac{M_H}{M_L} \right)_{it} + \theta \ln \left( \frac{M}{GDP} \right)_{it} + \alpha \Delta \ln \left( \frac{H}{L} \right)_{it} + \eta \Delta z_{it} + \gamma_i + \delta_t + \varepsilon_{it},
\]

(4)

where \(\gamma_i\) and \(\delta_t\) are country and period fixed effects, respectively, that are included in all specifications. We always include \(\Delta z_{it}\) in order to compare our mechanism to that in Zhu and Treffer (2005). Due to data constraints the change intervals \((\Delta)\) are not all perfectly aligned and are of different length, so country-specific intervals are grouped into five periods \((t)\), and changes are annualized. On average, each country is observed in three periods; in the appendix we list all country-specific intervals and common periods. We normalize overall capital imports by GDP. Variables not in changes are averaged within the period in order to be consistent with the annualized changes.

The coefficients of interest are \(\lambda\) and \(\theta\). Our hypothesis is that \(\lambda > 0\) and \(\theta = 0\).

Table 6 reports the results of estimating (4); we start with OLS and then in Section 3.4 we report TSLS estimates. Column 1 shows that the overall capital imports are not associated with changes in inequality, and column 2 shows that the import ratio is positively correlated with increases in the relative skilled wage.

Column 3 delivers the main message of this section: Even in the presence of overall capital imports, only the composition matters for changes in relative skilled wages, as we observe a positive and statistically significant coefficient to the latter in conjunction with a statistically insignificant one to the former. The partial \(R^2\) of the import ratio in this regression is 0.11 (this is the regression underlying Figure 1). The explanatory power of the import ratio is economically large: An increase from first to third quartile increases the change in the skill premium by two-thirds of the corresponding inter-quartile change, all else equal. The equivalent change in \(\Delta z\) has roughly half of this effect.\(^\text{19}\)

\(^{19}\)For \(\Delta z = 0.51 \times [0.014 - (-0.010)] = 0.012\), and for the log import ratio \(0.04 \times [0.290 - (-0.317)] = 0.024\); these represent 67% and 33% of the inter-quartile change in \(\Delta \ln \omega\) of \([0.036 - (-0.021)]\).
Column 4 shows that both the numerator $M_H$ and the denominator $M_L$ of the import ratio have explanatory power, in opposite directions. The coefficients to $\ln(M_H/GDP)$ and $\ln(M_L/GDP)$ are precisely estimated, and are relatively similar in absolute value, which is consistent with our assumption on the output elasticities and shares ($\beta$) in Section 2 above.

**Robustness checks for the capital composition mechanism**

In Table 7 we check the robustness of our results to adding a set of ancillary control variables (OLS estimates). If multinationals are important actors that import equipment, and employ superior disembodied technology that is also skill biased, then omitting their activity may induce a bias to the estimator of the coefficient to the import ratio. Note that both premises need to be true in order to create bias. In order to guard against this potential bias we add FDI position of U.S. multinational firms in the target country. If economic development is itself a skill-biased process that also increases incentives for more skill-complementary imports, then this would again induce bias; therefore we control for GDP per capita. Next, we add shares in value added of the industrial (manufacturing), government and services sectors. These may capture the effect of structural change on the skill premium. We also add a proxy for financial development (M3 money supply divided by GDP) to capture the ability to finance investment. We add the IPR protection index to correct for potential bias if exporters are less likely to export R&D-intensive equipment to countries that do not enforce IPR, which in turn have inherently less demand for skill.\(^{20}\) We control for the aggregate real capital stock, in order to show that the capital import composition mechanism operates independently of total net investment, not only independently of total capital imports.\(^{21}\) Due to data limitations, adding these variables reduces the sample size.

Overall, the results in Table 7 indicate that adding these control variables, either in changes—which we think is the more appropriate specification—or in levels (averages within periods), does not affect the main conclusion of this section. The point estimates of $\lambda$ do not change much and overall retain their precision. Only when we add all control variables in levels, the estimates become less precise, but this is hardly surprising since we are left with only 20 degrees of freedom. In contrast, it is reassuring that the estimates remain precise in all other specifications, where regressors are added one at a time.

Table 8 reports additional checks of the composition mechanism (OLS estimates). First, it is possible that capital is imported only to be used as an input into producing and exporting goods that fall within the same broad classification. This can happen due to the relatively high level

---

\(^{20}\)FDI, sectoral shares, financial development and intellectual property rights protection are also used by Caselli and Wilson (2004) as explanatory variables for capital imports.

\(^{21}\)Results are similar if instead of capital $K$ we use the capital-output ratio $K/Y$, $\ln(K/Y)$ or $d\ln(K/Y)$. The results are available by request.
of aggregation. In order to address this concern we add interaction terms for four countries that export significant amounts of capital goods: India, Korea, Mexico, and the Philippines. These countries have a correlation of less than 0.5 between net imports and implied investment; see Table 5.

Second, unobserved quality of capital imports may be a complementary mechanism to ours. If high income countries produce high quality products—overall, or within R&D ranks—and it is only high quality equipment that is complementary to skilled labor, then the results may be driven by imports from high income countries. In order to address this concern we identify the six largest capital exporters in our period of interest, based on Eaton and Kortum (2001): France, Germany, Italy, Japan, United Kingdom, and the United States. These are also high income countries that, presumably, produce high quality equipment. We construct separate capital import variables for flows originating in these six major producers and for flows that originate elsewhere, and fit specifications that are similar to the baseline results in Table 6.

Overall, the results in columns 3–8 in Table 8 do not indicate that the baseline results in Table 6 are driven by quality differentiation. In columns 3–4 we use only imports from countries other than the six major exporters (denoted "rest" in Table 8); in columns 5–6 we use only imports that originate from the six major exporters. These results are very similar to the baseline results in columns 3 and 4 of Table 6. In columns 7 and 8 we include capital imports originating from both types of sources. In column 7 both coefficients to overall capital imports are small and statistically insignificant. Although there is a large drop in the coefficient to the import ratio from high income countries, strong collinearity among the regressors prevents separate identification.

Finally (results reported in the appendix), the estimates of the main specifications of columns 3 and 4 of Table 6 are virtually unchanged, both in magnitude and statistical significance, if we normalize capital imports by population or total capital stock, rather than by GDP, or do not normalize at all. This is because capital imports have sufficient independent variation across countries and time, over and above their relationship to country size.

### 3.4 Capital imports and the skill premium: TSLS estimates

One potential concern in estimating (4) is endogeneity. For example, technological shocks that are not Hicks-neutral or are sector-specific may drive up both demand for skilled labor and imports of specific types of equipment. Another concern is omitted variable bias. For example, some...
intermediate inputs may be associated with specific imported equipment; if these inputs must be imported, and if they have systematic patterns of complementarity that correlate with those of capital equipment, then they can bias the estimator.\textsuperscript{25} Although we try to address these concerns with the ancillary controls variables in Table 7, they remain a threat to the internal validity of our estimates. An additional potentially endogenous variable in (4) is $\Delta \ln (H/L)$. We stress that since $\Delta \ln (H/L)$ is statistically uncorrelated with $\ln (M_H/M_L)$, any bias in the estimator of the coefficient to $\Delta \ln (H/L)$ does not affect the estimator of the coefficient to $\ln (M_H/M_L)$.

We construct the following instruments for capital imports, which are inspired by the methodology of Frankel and Romer (1999). As they do, we exploit exogenous geographic variation that affects bilateral trade flows—in our case dyadic distance—to construct instruments for trade flows by country—in this case imports. We estimate the following equation for capital type $H$, $L$ and for all capital imports separately for each importer, country and year:

$$\ln M_{oit} = \alpha_{it} + \delta_{it} \ln DISTANCE_{oi} + \varepsilon_{oit},$$ (5)

where $M_{oit}$ is capital imports of type $H$, $L$ or all capital imports, from origin country $o$ to destination country $i$ in year $t$, and $DISTANCE_{oi}$ is the distance (great circle) from $o$ to $i$. Here $\alpha_{it}$ captures destination-year specific effects, and $\delta_{it}$ allows the effect of distance to vary by destination and year. We estimate (5) separately for each $i$ and $t$. We then compute predicted values based on $\hat{\delta}_{it} \ln DISTANCE_{oi}$ and aggregate them to obtain $(\hat{M}_H^{gravity})_{it}$, $(\hat{M}_L^{gravity})_{it}$, and $(\hat{M})^{gravity}_{it}$.\textsuperscript{26} By replacing true values with these "gravity-predicted", we construct instruments for $\ln (M_H/M_L)_{it}$, $\ln (M_H/GDP)_{it}$, $\ln (M_L/GDP)_{it}$, and $\ln (M/GDP)_{it}$.

Note that we are not interested in estimating the causal effect of distance in (5). Instead, we wish to use exogenous variation in distance in order to extract exogenous variation to be used as an instrument that satisfies exclusion restrictions. In the appendix we show that omitted variables in (5) are unlikely to threat the exogeneity of the instruments, thus calculated. This depends on whether the covariance of such omitted variables with distance across origin countries varies systematically with omitted variables in (4), or with $\Delta \omega_{it}$ directly. While impossible to prove or

\textsuperscript{25}To the extent that this is true, one can interpret our estimates as inclusive of this secondary effect. We do not include imports of intermediate inputs in (4) for two reasons. First, it is not obvious how to estimate complementarities for intermediate inputs: They are variable inputs, not quasi-fixed, and therefore without price data we cannot classify them by degree of complementarity. Second, the bulk of intermediate inputs are produced and supplied domestically, as many studies point out, for example Amiti and Cameron (2012). Therefore, imported inputs do not satisfy our identifying assumption, that imports are a good measure of flows of total usage (in our case, investment).

\textsuperscript{26}Distance data are from CEPII, http://www.cepii.fr/CEPII/fr/bdd_modele/presentation.asp?id=6. We first take exponents of the distance-predicted values $\hat{M}_{oit} = e^{\ln \hat{M}_{oit}}$, then sum over all origins $\hat{M}_{it} = \sum_o \hat{M}_{oit}$. We neglect terms that multiply $e^{\ln \hat{M}_{oit}}$ (for example, $e^{1/2 \varepsilon^2}$, if $\varepsilon$ is distributed normal) because they are constant and, therefore, when we take logs and use as instruments they will be absorbed by fixed effects in the first stage.
disprove, it is difficult to think of omitted variables with such properties.

Columns 5 and 6 of Table 6 report the IV estimates. In all specifications we treat all capital imports as endogenous and instrument for them. Second stage results show that the magnitudes of the coefficients of interest increase somewhat, and consequently their explanatory power. For example, a one standard deviation increase in the import ratio now increases the change in the skill premium by approximately two-thirds of a standard deviation, significantly more than $\Delta z$. \footnote{For $\Delta z \times 0.52 \times 0.032 = 0.0166$, and for the log import ratio $0.05 \times 0.425 = 0.0212$; these represent 50\% and 64\% of the standard deviation of $\Delta \ln \omega$ (0.033).}

In Panel B of Table 6 we report first stage estimates and statistics. The signs of the coefficients to the instruments are as expected, having a strong positive effect on the corresponding type of capital imports. Overall, the instruments are strong: The Shea (1997) partial $R^2$ are large and not substantially lower than the usual partial $R^2$. Although not an appropriate statistic when there is more than one endogenous instrumented variable (Stock and Yogo (2002)), we report the partial $F$-stat and find it reasonably high in all cases.

To summarize, we find that the composition of capital imports matters, not the overall quantity. These results hold both when using OLS and TSLS estimators, and also survive a battery of other robustness checks. Imports of R&D-intensive equipment are associated with increases in the skill premium; imports of less innovative capital equipment are associated with decreases in the skill premium. In the next section we explain why this is the case.

4 Complementarity of capital to skilled and unskilled labor

In this section we explain why the capital import ratio explains changes in the skill premium. Since Griliches (1969), capital is considered complementary to skilled labor. With some reservations about robustness, other studies generally confirm the capital-skill complementarity hypothesis.\footnote{See Fallon and Layard (1975), Bergstrom and Panas (1992), Duffy, Papageorgiou, and Perez-Sebastian (2004).} However, these studies (including Griliches') investigate complementarity to aggregate measures of capital; they do not consider the composition of capital. In this section we establish that R&D-intensive capital equipment is complementary to skilled labor, while less innovative capital equipment is complementary to unskilled labor.\footnote{This in itself can help explain the sensitivity of the results in Duffy, Papageorgiou, and Perez-Sebastian (2004): The composition and, hence, overall degree of complementarity of capital is not the same across countries in their panel.} To be precise, when we say that a type of capital is complementary to a class of workers, this is a relative statement. For example, R&D-intensive capital equipment is more complementary to skilled labor than to unskilled labor.

The estimation employs data from the EU-KLEMS data set (O’Mahony and Timmer (2009)),

\footnote{\textsuperscript{27}For $\Delta z \times 0.52 \times 0.032 = 0.0166$, and for the log import ratio $0.05 \times 0.425 = 0.0212$; these represent 50\% and 64\% of the standard deviation of $\Delta \ln \omega$ (0.033).}

\footnote{\textsuperscript{28}See Fallon and Layard (1975), Bergstrom and Panas (1992), Duffy, Papageorgiou, and Perez-Sebastian (2004).}

\footnote{This in itself can help explain the sensitivity of the results in Duffy, Papageorgiou, and Perez-Sebastian (2004): The composition and, hence, overall degree of complementarity of capital is not the same across countries in their panel.}
which includes mostly high income countries. The complementarity estimates in these data are relevant for developing countries, which import most of their capital equipment (as we establish above) from high income countries (as shown in Eaton and Kortum (2001)). The validity of this exercise for developing countries relies also on similarity in responses of relative demand for skill in different settings. We therefore estimate these responses using two definitions of skilled labor, one of which is more relevant for developing countries.

We follow standard methodology and estimate a skilled labor share equation, e.g., as in Berman, Bound, and Griliches (1994). Assume a translog cost function where there are four inputs: Skilled and unskilled labor, and two types of capital. If capital is quasi-fixed, skilled and unskilled labor are variable factors, and production exhibits constant returns to scale, then cost minimization yields the following relationship

\[
S = \alpha + \beta \ln \left( \frac{w_H}{w_L} \right) + \gamma_1 \ln \left( \frac{K_1}{Y} \right) + \gamma_2 \ln \left( \frac{K_2}{Y} \right),
\]

where \(S\) denotes the wage bill share of skilled labor, \(w_H\) and \(w_L\) are wages of skilled and unskilled labor, \(K_1\) and \(K_2\) are two types of capital, and \(Y\) denotes output. Details on the derivation are in the appendix. The \(\gamma_j\) coefficients indicate the type and magnitude of complementarity with skilled labor: \(\gamma_j > 0\) implies stronger complementarity to skilled labor, while \(\gamma_j < 0\) implies stronger complementarity to unskilled labor.

We estimate versions of (6) by capital type,

\[
S_{it} = \beta \ln \left( \frac{w_H}{w_L} \right)_{it} + \gamma_j \ln \left( \frac{K_j}{Y} \right)_{it} + \gamma_{-j} \ln \left( \frac{K_{-j}}{Y} \right)_{it} + \alpha_i + \delta_t + \epsilon_{it},
\]

where \(K_j\) is capital of type \(j\) and \(K_{-j}\) captures the sum of all other capital types. Here \(\alpha_i\) and \(\delta_t\) are country and year fixed effects, respectively. The fixed effects capture, \textit{inter alia}, unobserved disembodied non-neutral technological change. We estimate (7) using two independent sources of data on capital stocks: EU-KLEMS and OECD. Although the categories of capital are broad (five or nine groups), and may include sub-categories that are more, or less, complementary to skill, the classification is informative and captures important qualitative differences.

4.1 Complementarity estimates using EU-KLEMS data

Our first set of estimates uses an unbalanced panel of 14 countries in 1970–2005 from the EU-KLEMS data set. The EU-KLEMS data set reports data on capital stocks for five distinct capital groups (\(j\)): (1) Computing equipment, (2) communication equipment, (3) software capital, (4) transport equipment, and (5) machinery. First we estimate (7) separately for each capital group.
Then we aggregate into two groups: ICT (information and communication technology capital, groups 1–3) and non-ICT (groups 4–5); see Table 1. Finally, we also estimate (7) using the total capital stock.30

The EU-KLEMS disaggregates workers into three groups: High skilled, medium skilled, and low skilled. The definition of high skilled workers is consistent across countries, and implies at least a university-equivalent bachelors degree. The definitions of the other two groups vary somewhat across countries, but are consistent over time within a country. Medium skilled workers do not attain a university-equivalent bachelors degree, but complete high-school and possibly a non-university vocational degree; low skilled workers do not complete high school. We use two definitions of skill in the implementation of (7): High (narrow definition), and high + medium (broad definition). This facilitates two goals. First and foremost, the broad definition is more relevant for developing countries. Second, it allows checking the robustness of the complementarity results.31 Wage bill shares for all three groups are given in the data directly. Wages are given by wage bills divided by hours worked. We follow standard methodology and estimate (7) by TSLS, instrumenting for the capital shares using their values in the previous period. Results are not sensitive to the number of lags included. We report standard errors using country level clustering.

The results in Table 9 show a clear pattern: On one hand, computing equipment, communication equipment, and software capital are complementary to skilled workers; on the other hand, transport equipment, and machinery are complementary to unskilled workers. When ICT and non-ICT capital groups are included, we confirm the results for their subcomponents: ICT capital is complementary to skilled workers; non-ICT capital is complementary to unskilled workers. These results hold whether we use the narrow or the broad definition of skill. Since the year fixed effects add little explanatory power, fitting (7) without them yields virtually the same results. Taking changes in (6) and estimating the resulting equation by TSLS with country fixed effects—using lagged variables in changes as instruments—yields remarkably similar results.32

In the last column of Table 9 we also estimate that the aggregate capital stock is complementary to skilled labor. We find it comforting that we can replicate previous findings. This should not be confused with the results in Section 3: The composition of the aggregate capital stock and investment in countries in the EU-KLEMS sample—which are mostly developed economies—is much more R&D intensive, with a higher share of ICT, relative to the sample of developing countries.

---

30 See appendix for details on the sample used in the complementarity estimation. In the appendix we also report shares of capital types in the aggregate capital stock, and changes thereof, for each country in the sample.
31 Duffy, Papageorgiou, and Perez-Sebastian (2004) find the international empirical evidence in favor of the capital-skill complementarity hypothesis at the aggregate level most convincing when skilled workers are defined broadly, as high + medium.
32 These results are reported in the appendix.
that we examine above. Moreover, developed economies import a much smaller share of their capital investment.

4.2 Complementarity estimates using OECD data

We wish to estimate (7) using the nine groups—classified by R&D intensity—that are used above in Section 3, but the EU-KLEMS data on capital stocks are not classified according to ISIC.\textsuperscript{33} Since there are no readily available capital stocks that are classified by ISIC, we estimate these using OECD data.\textsuperscript{34}

The OECD data include production $Y$, imports $M$, and exports $X$, by ISIC in 1970–2005. This allows estimating implied investment $I$ for each of the nine capital groups

$$I_{g,t} = Y_{g,t} + M_{g,t} - X_{g,t},$$

where $g = 1, 2, ... 9$ denotes R&D intensity rank. We then use the perpetual inventory method to estimate capital stocks

$$K_{g,t+1} = (1 - \delta_g)K_{g,t} + I_{g,t}.$$

We estimate capital stocks in the initial year by type as

$$K_{g,0} = \frac{I_{g,0}}{\delta_g}.$$ 

Depreciation estimates by capital type $\delta_g$ are from Fraumeni (1997), and are based on U.S. data.\textsuperscript{35} We estimate (7) using the same methodology and data as above, except that we use our estimated capital stocks by R&D intensity.\textsuperscript{36}

Table 10 reports the complementarity estimation results, which largely confirm the results in Table 9. The most R&D-intensive capital types (aircraft equipment, office, computing and accounting machinery, communication equipment) are complementary to skilled labor. Of the other six relatively less R&D-intensive capital types, four (electrical equipment excluding communication, non-electrical equipment, other transportation equipment, fabricated metal products) are complementary to unskilled labor. The Spearman rank correlation between the complementarity coefficient and the R&D rank is $-0.95$ (p-value = 0.0001). Motor vehicles and professional goods are not more

\textsuperscript{33}Based on EU-KLEMS documentation, it is not obvious how to map all nine disaggregate ISIC capital types into the EU-KLEMS classification or even into broad ICT and non-ICT groups.

\textsuperscript{34}OECD data from StatsExtract data available at: http://stats.oecd.org/.

\textsuperscript{35}These are the same depreciation rates that are used in the EU-KLEMS for construction of capital stocks by group.

\textsuperscript{36}The sample for which we calculate capital stocks using OECD data is reported in the appendix, where we also report shares of capital types in the aggregate capital stock, and changes thereof, for each country in the sample.
complementary to either class of labor when using the narrow definition of skill. However, the results using the broad definition of skill make us decide to include the latter two types of capital in $M_H$ in the import composition estimation in Section 3 above.

When we aggregate the R&D-intensive, skill-complementary, capital groups ($K_H$), and the R&D-unintensive, unskilled-complementary, capital groups ($K_L$), we confirm the results for their subcomponents: $K_H$ is complementary to skilled workers; $K_L$ is complementary to unskilled workers. These results are similar when we use the broad definition of skill (high + medium).

Overall, using several specifications and data sources, we find strong evidence for capital-skill complementarity for R&D-intensive, innovative capital types; we find that less innovative and relatively R&D-unintensive equipment is complementary to unskilled labor. This is the reason that the composition of capital imports (which stands in for investment), and not the overall quantity, affects the skill premium.

## 5 Trade liberalization and changes in the composition of capital imports

We argue above that an increase in the share of R&D-intensive, skill-complementary capital in total capital imports increases relative demand for skilled labor and therefore raises the skill premium. During 1983–2000, a period of trade liberalization in the sample of developing countries that we study, the share of $M_H$ in our sample increases by 3.5% on average, commensurate with an equal drop in the share of $M_L$—and there is significant variation in this change across countries. However, this does not necessarily imply that trade liberalization increases the skill premium through this channel. This is a difficult question to answer, but in this section we provide some evidence that is consistent with this hypothesis.\(^{37}\)

The mechanics of trade liberalization work through changes in domestic relative prices of $M_H$ versus $M_L$. Using the framework of Section 2 we can derive an approximation for $\ln \left( \frac{M_H}{M_L} \right)$ as (see appendix)

$$
\Delta \ln \left( \frac{C}{K} \right) = \rho \Delta \ln \left( \frac{H}{L} \right) - \varphi \Delta \ln \left( \frac{r_C}{r_K} \right),
$$

where $r_C/r_K$ is the price of $C$ relative to $K$, $\rho = \beta (\sigma - 1) / [\sigma - (1 - \beta) (\sigma - 1)] > 0$ and $\varphi = \ldots$

\(^{37}\) Alfaro and Hammel (2007) argue that in the same period that we study stock market liberalizations are associated with increases in imports of capital equipment. This channel is complementary to liberalization in goods trade—both reduce the cost of purchasing capital equipment abroad. The question here is whether the effect of these reforms is greater on $M_H$ versus $M_L$. Larrain (2013) argues that capital account liberalization in industrialized countries increased inequality by making available external funding for capital investment. He does not distinguish between different types of capital, but finds stronger effects in industries that exhibit stronger aggregate capital-skill complementarity and more external finance reliance. However, the estimated magnitudes are small. In contrast, we focus on the mechanism, in a set of less-developed countries.
We decompose each capital import price \( r_j \) into four components: A "free on board" (FOB) price at the source \( r_j^* \), ad valorem tariffs \( \tau_j \), specific (transportation) freight costs \( \tilde{f}_j \), and other ad valorem trade barriers \( b \), so that

\[
\frac{r_C}{r_K} = \frac{(r_C^{*} + \tilde{f}_C)}{(r_K^{*} + \tilde{f}_K)} \frac{(1 + b_C)}{(1 + b_K)} = \frac{r_C^{*}}{r_K^{*}} \frac{(1 + f_C)(1 + \tau_C)(1 + b_C)}{(1 + f_K)(1 + \tau_K)(1 + b_K)},
\]

where \( f_j \equiv \tilde{f}_j/r_j^{*} \) is the ad valorem equivalent freight cost. Although freight costs are usually denominated in specific (per unit, not per value) terms in the real world, a more meaningful way to analyze their impact on trade flows is to transform them into ad valorem terms (see Hummels and Skiba (2004) and Hummels (2007)). Most countries, with few exceptions, apply tariffs to the transport-inclusive CIF (cost, insurance and freight) price of a product, as in (8). In the appendix we report separate results for 12 countries who do not follow this rule, and instead apply tariffs to FOB prices.\(^{38}\)

We demonstrate that \( 1 + f_j \), \( 1 + \tau_j \) and the product of \( (1 + f_j)(1 + \tau_j)(1 + b_j) \) all fall proportionately more for \( M_H \) versus \( M_L \)—both in a broad set of countries, and in our sample of developing economies, where data permits testing this—all of which reduce \( r_C/r_K \), given \( r_C^{*}/r_K^{*} \). We keep the exposition of results to a minimum; full statistical outputs are available upon request.

### 5.1 Tariffs on \( M_H \) fall proportionately more relative to \( M_L \)

We start by demonstrating that on average, \( 1 + \tau_C \) falls proportionately more than \( 1 + \tau_K \), i.e., their ratio falls. We use tariff data from the TRAINS data set in 1988–2010, which gives us 2,826 observations over 169 countries.\(^{39}\) We fit the following regression

\[
\ln(1 + \tau_{it}^{j}) = \delta_1 t + \delta_2 \left[ I_{j \in M_H} \right] \cdot t + \delta_3 I_{j \in M_H} + \alpha_i + \varepsilon_{it},
\]

where \( i \) is a country, and \( j \in \{M_H, M_L\} \) indicates that a product is either in the \( M_H \) or \( M_L \) capital import group, and \( \alpha_i \) is a country fixed effect. We cluster standard errors by country. Developing countries are under-represented in TRAINS, but less so over time; therefore \( t \) denotes time since country \( i \) enters the data set, which takes into account evolving coverage. We cluster standard errors by country in order to take this into account.

---

\(^{38}\) These 12 countries are: Afghanistan, Australia, Botswana, Canada, Democratic Republic of the Congo, Lesotho, Namibia, New Zealand, Puerto Rico, South Africa, Swaziland, and the United States. In these countries, which we call the "FOB sample", tariffs are applied to the FOB (free on board) price, exclusive of freight costs. See http://export.customsinfo.com/ and http://export.gov/logistics/eg_main_018142.asp. We thank Robert Feenstra for this reference.

\(^{39}\) TRAINS (Trade Analysis and Information System) data downloaded from http://wits.worldbank.org/wits/.
The point estimate of $\delta_1$ is $-0.004$ and the point estimate of $\delta_2$ is $-0.001$, both statistically significant at the 1% level. Tariffs fall over time, but tariffs on $M_H$ more so. Over the sample, $\delta_2 = -0.001$ translates into a relative reduction of 0.022. We also fit specifications similar to (9) with time dummies instead of linear time trends. Those regressions confirm the previous conclusion, but also illustrate that the drop is driven mostly by countries with long representation (large $t$).40

5.2 Transport costs of $M_H$ fall proportionately more relative to $M_L$

We now use data from Hummels (2007) on ad valorem freight costs for shipments into the U.S. 1983–2004, and demonstrate that transportation costs fall more for $M_H$ than for $M_L$ (i.e. $1 + f_C$ falls proportionately more than $1 + f_K$). We also find that effect is stronger for shipments by air relative to shipments by sea. In these data, the share of air shipments for $M_H$ doubles from 20.5% in 1983 to 41% in 2004. The share of air shipments for $M_L$ fluctuates around 45%.

We fit the following regression

$$\ln (1 + f_j) = \delta_1 t(j) + \delta_2 [I(j \in M_H) \cdot t(j)] + \delta_3 I(j \in M_H) + \gamma \ln (w/v)_j + \alpha_{s(j)} + \varepsilon_j ,$$

(10)

where $j$ is a shipment, $j \in \{M_H, M_L\}$ indicates that a product is either in the $M_H$ or $M_L$ capital import group, and $w/v = \text{denotes the weight per dollar value of shipment}$. Here $\alpha_{s(j)}$ is a fixed effect for all shipments $j$ imported from source $s$ (which absorbs the effect of distance, inter alia), and $t(j)$ indicates that shipment $j$ is observed in year $t$. In the estimation we weigh observations by shipment value and cluster standard errors by source country. When we estimate (10) for sea shipment we also control for the share of containerized trade in the shipment. We fit (10) using data on shipments of capital goods, of which 220,568 are by air and 181,159 are by sea. We weigh observations by value, because we are interested in inferences about total value by import type, not average shipment (results are qualitatively similar without weighting).

For air shipments, the point estimate of $\delta_1$ is $-0.0005$ and the point estimate of $\delta_2$ is $-0.0005$, both statistically significant at the 1% level.41 Air freight costs fall over time, but at double the rate for $M_H$. Over the sample, $\delta_2 = -0.0005$ translates into a relative reduction of 0.0105. For sea shipments, the point estimate of $\delta_1$ is $-0.0006$ and the point estimate of $\delta_2$ is $-0.0003$, both statistically significant at the 1% level.42 Sea freight costs fall over time, but faster for $M_H$. Over the sample, $\delta_2 = -0.0003$ translates into a relative reduction of 0.0063. We also fit specifications

40Time dummies for $M_H$ become increasingly large, negative and statistically significant from 8 years in the sample and on.
41If we drop $\ln (w/v)$ the point estimates of $\delta_1$ and $\delta_2$ both become $-0.0006$ respectively.
42If we drop $\ln (w/v)$ and the containerization indicator the point estimates of $\delta_1$ and $\delta_2$ become $-0.0005$ and $-0.0004$, respectively.
similar to (10) with time dummies instead of linear time trends. Year fixed effects can absorb better global changes in fuel prices. Those regressions confirm the previous conclusion, but also show that the relative reductions happen continuously over time.

5.3 Barriers to trade for \( M_H \) fall relative to \( ML \)

Finally, we demonstrate that bilateral barriers to trade for \( M_H \) falls relative to \( M_L \). The data on tariffs do not have good coverage of developing countries, and the data on freight costs pertain only to U.S. imports, so the following exercise helps paint a more complete picture.

We estimate the following gravity equation

\[
m_{sit}^j = \beta_1 t + \beta_2 I(m_{sit}^j \in M_H) + \beta_3 \left[ I(m_{sit}^j \in M_H) \cdot t \right] + (\chi_s^0 + \chi_s^1 \cdot t) + (\eta_i^0 + \eta_i^1 \cdot t) + \epsilon_{sit}^j ,
\]

where \( m_{sit}^j \) are log capital imports from source \( s \) to importer \( i \) in time \( t \) of capital type \( j \in \{ M_L, M_H \} \); and \( I(m_{sit}^j \in M_H) \) indicates whether \( m_{sit}^j \) is of type \( M_H \) (= 1) or not (= 0). Exporter and importer fixed effects—\( \chi_s^0 \) and \( \eta_i^0 \)—and exporter and importer-specific time trends—\( \chi_s^1 \cdot t \) and \( \eta_i^1 \cdot t \)—respectively, capture levels and trends in demand conditions in the importer countries and in technology in the source country. It is important to see that the latter ensure that \( \beta_1, \beta_2 \) and \( \beta_3 \) are identified only by bilateral variation in barriers to trade. Here \( \beta_1 \) captures overall trends, and \( \beta_2 \) captures the permanent differential level of bilateral barriers to trade for \( M_H \). The coefficient of interest is \( \beta_3 \), which captures the differential change in bilateral barriers to trade for \( M_H \). This coefficient absorbs the differential trend in the effect of all bilateral trade impediments (\textit{inter alia}, distance, language, colonial ties, tariffs, freight costs, etc.).

We estimate (11) by OLS, clustering standard errors by country-pair, using import data in 1984–1999, for 157 countries (136,786 observations).\(^{43}\) We estimate \( \beta_3 = 0.0126 \) (highly statistically significant), which indicates that bilateral barriers to trade fall for \( M_H \) relative to \( M_L \). When we restrict the importers to the set of developing countries we study above in Section 3 (with no restriction on exporters), we estimate \( \beta_3 = 0.017 \) (highly statistically significant).

These results are confirmed when we estimate gravity equations separately for each year in 1984–1999 (which is the most appropriate way to do this; see Head and Mayer (2014)):

\[
m_{si}^j = \beta \cdot I(m_{si}^j \in M_H) + \chi_s + \eta_i + \epsilon_{si}^j .
\]

The increase over time in \( \beta \) is gradual and its trajectory over time is virtually the same as the estimate of \( \beta_3 \) in (11). We also estimate (12) with a Heckman correction for sample selection along the lines of Helpman, Melitz, and Rubinstein (2008), using their common religion index as

\(^{43}\)See appendix for the list of countries in the sample.
an excluded variable in the selection equation. This increases the magnitude of the coefficients to \(I(m_{si}^{2} \in M_H)\) somewhat, but hardly affects their trend over time. To summarize, bilateral barriers to trade for \(M_H\) fall relative to \(M_L\), regardless of how we estimate this.

What do these estimates imply for changes in inequality in developing countries? The estimate \(\hat{\beta}_3 = 0.017\) implies an increase in \(\ln M_H - \ln M_L = \ln(M_H/M_L)\) of 0.255 from 1984 to 1999, which, given \(\hat{\lambda} = 0.04\) (OLS) translates into an annual increase in \(w_H/w_L\) of approximately 1.02% per year; if we use \(\hat{\lambda} = 0.05\) (TSLS), the implied annual increase in \(w_H/w_L\) is 1.224%, which is about one third of the inter-quartile change (see Table 2). Thus, differential reductions in bilateral trade resistance for developing countries have a large effect on changes in relative wages of skilled workers in these countries. According to (8), the remainder can be attributed to changes in supply conditions, namely the drop in the relative price of skill-complementary equipment versus other capital.\(^{44}\)

6 Conclusion

Empirical investigations of episodes of trade liberalization usually do not find large effects on the skill premium. One reason is that these studies focus on traded final goods (e.g., Zhu and Trefler (2005), Verhoogen (2008), Bustos (2011)) or intermediate inputs (e.g. Feenstra and Hanson (1996), Amiti and Cameron (2012)), and typically focus on mechanisms that directly affect only the traded sector. In this paper we show that the composition of capital imports has strong explanatory power for changes in the skill premium in a sample of developing countries. In addition, we argue that trade liberalization can shift the distribution of capital imports in a way that increases the skill premium. Thus, we provide a novel explanation for the increase in the skill premium in developing countries that liberalized trade.

We find that when the composition of capital imports is more R&D intensive, the skill premium increases, whereas when it is less R&D intensive the skill premium falls. This is because R&D-intensive capital is complementary to skilled labor, whereas R&D-unintensive capital is complementary to unskilled labor. To our best knowledge, we are the first to argue that some types of capital are more complementary to unskilled workers. The composition of imports has a first order effect on the composition of capital stocks in developing countries, because they import most of their capital and produce little of it domestically. The composition of imports largely determines the composition of investment, and, in turn, the capital stock. This is why the capital import ratio—a measure of import composition—has such strong explanatory power. We estimate that an

\(^{44}\)Of course, this is less relevant for countries that also produce much of the capital that they use.
increase in the import ratio from the first to the third quartile increases the rate of change in the skill premium by two thirds of the inter-quartile difference.

We argue that trade liberalization has shifted the distribution of import composition towards more skill-complementary capital. First, tariff reductions and reductions in freight costs have been larger, on average, for skill-complementary equipment. In addition, bilateral trade barriers fall more rapidly for imports of skill-complementary equipment relative to unskilled-complementary equipment. This shifts the composition of capital imports towards skill-complementary equipment—and causes an increases in the skill premium. We estimate that this effect is equivalent to about a third of the inter-quartile difference in changes in the skill premium.

Our results highlight the importance of the composition of imports, not just aggregate quantities. While we focus here on capital imports, we believe that the mechanism that we investigate—composition together with patterns of complementarities—can help explain results in other papers, e.g. Amiti and Cameron (2012). In addition, the importance of composition raises concerns for the validity of estimates of the contribution of capital imports to increases in the skill premium in quantitative trade models that have no role for composition. Since the composition of capital imports varies across countries, so does the effective complementarity of aggregate capital imports. Such quantitative analyses—in particular, Burstein, Cravino, and Vogel (2013) and Parro (2013)—can be modified to take into account capital import composition, together with the pattern of complementarities that we uncover. This can lead to a better understanding of the role of capital imports in affecting the distribution of the gains from trade.
Appendix

A Detailed descriptions of ISIC capital goods classifications

Capital goods are defined as ISIC rev.2 category 38, "Manufacture of Fabricated Metal Products, Machinery and Equipment". Here we list capital goods from highest to lowest R&D intensity based on Caselli and Wilson (2004) with corresponding ISIC in parentheses:

1. Aircraft equipment (3845): Aircraft and related parts.
3. Communication equipment (3832): Semiconductors, wire and wireless telephone equipment, radio and TV sets, audio recording equipment, signaling equipment, radar equipment.
5. Electrical equipment, excluding communication equipment (383 without 3832): Electrical industrial machinery, electrical appliances, and other electrical apparatus.
7. Non-electrical equipment (382 without 3825): Engines and turbines, agricultural machinery (including tractors, excluding metal tools), metal and wood-working machinery, industrial trucks, military ordinance (including tanks).
8. Other transportation equipment (3842, 3844, 3849): Railroad equipment, motorcycles and bicycles, wagons and carts.

B Data

B.1 Inequality regressions

Sample

The sample is an unbalanced panel covering 1983–2000 with varying time periods for each country, based on data availability for wage data, and builds on, and extends, the sample of Zhu and Trefler (2005). All countries in this sample have real GDP per capita in 1980 below $14,000 in 1980 dollars. The sample is further restricted by data availability.

Since the intervals do not perfectly overlap for all countries, we group country-specific intervals into five periods. Each interval was classified to the period with which it has the largest overlap. These are: 1983–1986 (10 country observations), 1986–1989 (14 country observations), 1990–1993 (16 country observations), 1993–1997 (19 country observations), and 1997–2000 (4 country observations). On average, each country is observed in three periods. These periods underlie the time fixed effects in all estimations of equation 4.

Variable definitions

Change in the logarithm of skilled relative wage, $\Delta \ln \omega$: Defined as the wage ratio of manufacturing workers in non-production occupations (managers, professionals, technicians, and clerks) to manufacturing workers in production occupations (craft workers, operators, and laborers). Source: International Labour Organization.

Change in logarithm of relative supply of skill (skill abundance), $\Delta \ln (H/L)$: relative supply of skill is measured by the ratio of skilled to unskilled population, aged 25 and above. The skilled group is defined as those having at least secondary education. Source: Barro and Lee (2013).

Shift in export shares, $\Delta z$: Consider the area under the cumulative distribution function of export shares to OECD countries with 1980 real GDP per capita exceeds $14,000 (in 1980 dollars), where industries are ranked by their skill intensity. $\Delta z$ is the difference in this area between the last and first year in each period. More formally, rank all industries for some country by skill intensity (based on the ratio of non-production workers to production workers) and normalize to 1. Define this rank as $r \in [0,1]$. The export share of each industry in time $t$ is $x_t(r)$, where only exports to OECD countries with real GDP per capita in 1980 above $14,000 in 1980 dollars.

$\Delta z_t = \int_0^1 \int_0^r x_t(s) \frac{ds}{dr} dr - \int_0^1 \int_0^{r-1} x_{t-1}(s) \frac{ds}{dr} dr$. Source: Zhu and Treffer (2005).

$GDP, \text{Population, Industrial/Government/Services share (value added shares in GDP)}$. Source: World Bank, World Development Indicators.

$Aggregate capital stocks$: Source: Penn World Tables, Version 6.1 (Heston, Summers, and Aten (2012)).

$Intellectual property rights protection index$: This index characterizes strongly patent rights are protected. It is constructed using a coding scheme applied to national patent laws, examining five distinct categories. Source: Ginarte and Park (1997), updated by Park (2008).

$Financial development$: M3 money supply as a fraction of GDP. Source: World Bank, World Development Indicators.

Data from Feenstra, Lipsey, Deng, Ma, and Mo (2005)

Imports of R&D-intensive capital: Imports of R&D-intensive capital are averaged within each time interval. R&D-intensive capital is an aggregated group that includes the following ISICs: computing equipment (3825), communication equipment (3832) aircraft equipment (3845), motor vehicles (3843), and professional goods (385).

Imports of R&D-unintensive capital: Imports of R&D-unintensive capital are averaged within each time interval. R&D-unintensive capital is an aggregated group that includes the following ISICs: fabricated metal products (381), non-electrical equipment (382 without 3825), electrical equipment (383 without 3832), and other transportation equipment (3842, 3844, 3849).

Aggregate capital imports: Imports of aggregate capital are averaged within each time interval. Aggregate capital is an aggregated group that includes all nine capital groups.

The capital import ratio: The capital import ratio is defined as imports of R&D-intensive capital (averaged within each time interval) divided by R&D-unintensive capital (averaged within each time interval).
Capital goods are defined as ISIC rev.2 category 38, "Manufacture of Fabricated Metal Products, Machinery and Equipment".

C Derivations for analytical framework section

There are two types of capital—$C$ and $K$ (think computers and tractors, respectively)—and two types of labor—skilled $H$ and unskilled $L$. The aggregate production function is given by

$$Q = \left[ \delta X^{\frac{s-1}{s}} + (1 - \delta) Y^{\frac{s-1}{s}} \right]^{\frac{s}{s-1}},$$

where

$$X = H^\beta C^{1-\beta},$$

$$Y = L^\beta K^{1-\beta}.$$
\( \beta \in (0, 1) \) and \( \sigma > 1 \).

Workers supply labor—either \( H \) or \( L \)—inelastically. Denote the wage of skilled labor by \( w_H \) and the wage of unskilled labor by \( w_L \). Denote the price of capital as \( r_j \) for \( j \in \{ C, K \} \). Competitive factor markets imply that factors are paid the value of their marginal product:

\[
\begin{align*}
\frac{\partial Q}{\partial H} &= \frac{\sigma}{\sigma - 1} \frac{\delta \sigma - 1}{\sigma} X \sigma - 1 \beta X_H = \beta \delta Q^X \sigma - 1 X_H^{-1} = w_H \\
\frac{\partial Q}{\partial C} &= \frac{\sigma}{\sigma - 1} \frac{\delta \sigma - 1}{\sigma} X \sigma - 1 (1 - \beta) \frac{X}{C} = (1 - \beta) \delta Q^X \sigma - 1 C^{-1} = r_C \\
\frac{\partial Q}{\partial L} &= \frac{\sigma}{\sigma - 1} \frac{\delta \sigma - 1}{\sigma} Y \sigma - 1 \beta \frac{Y}{L} = \beta (1 - \delta) Q^Y \sigma - 1 L^{-1} = w_L \\
\frac{\partial Q}{\partial K} &= \frac{\sigma}{\sigma - 1} \frac{\delta \sigma - 1}{\sigma} Y \sigma - 1 (1 - \beta) \frac{Y}{K} = (1 - \beta) (1 - \delta) Q^Y \sigma - 1 K^{-1} = r_K.
\end{align*}
\]

The relative wage of skilled workers is

\[
\omega \equiv \frac{w_H}{w_L} = \frac{\delta X \sigma - 1 H^{-1}}{(1 - \delta) Y \sigma - 1 L^{-1}} = \frac{\delta}{1 - \delta} \left( \frac{H^\beta C^{1 - \beta}}{L^\beta K^{1 - \beta}} \right)^{\sigma - 1} \left( \frac{H}{L} \right)^{-1}
\]

as in the main text. In order to derive the expression for \( C/K \) we start with

\[
\begin{align*}
\frac{r_C}{r_K} &= \frac{\delta X \sigma - 1 C^{-1}}{(1 - \delta) Y \sigma - 1 K^{-1}} = \frac{\delta}{1 - \delta} \left( \frac{H^\beta C^{1 - \beta}}{L^\beta K^{1 - \beta}} \right)^{\sigma - 1} \left( \frac{C}{K} \right)^{-1} \\
&= \frac{\delta}{1 - \delta} \left( \frac{H}{L} \right)^{\beta (\sigma - 1)} \left( \frac{C}{K} \right)^{-\frac{\beta (\sigma - 1)}{\sigma}} \left( \frac{r_C}{r_K} \right)^{-\frac{\beta (\sigma - 1)}{\sigma}}
\end{align*}
\]

which gives

\[
\frac{C}{K} = \left( \frac{\delta}{1 - \delta} \right)^{\frac{\sigma}{\sigma - (1 - \beta) (\sigma - 1)}} \left( \frac{H}{L} \right)^{\frac{\beta (\sigma - 1)}{\sigma - (1 - \beta) (\sigma - 1)}} \left( \frac{r_C}{r_K} \right)^{-\frac{\beta (\sigma - 1)}{\sigma - (1 - \beta) (\sigma - 1)}}.
\]

Taking logs and then first differences gives the equation used in the main text.

Here we show that \( \sigma - (1 - \beta) (\sigma - 1) > 0 \) for \( \beta \in (0, 1) \) and \( \sigma > 0 \), regardless of whether \( \sigma \) is greater than unity or not. For \( \sigma > 1 \) we have a positive fraction, \( (1 - \beta) \), times a positive number smaller than \( \sigma \), \( (\sigma - 1) \), which together give \( (1 - \beta) (\sigma - 1) < \sigma \). When \( \sigma < 1 \) the product \( (1 - \beta) (\sigma - 1) < 0 \), but then deducting a negative number from a positive one remains positive.

### D Contribution of changes in capital stocks to changes in relative demand for skill via changes in industry sizes

We draw on the EU-KLEMS data set. For each country and industry in the data set we collect the following variables for 1983–1997 (the sample in the main analysis):

29
• The percent contribution to value added growth of two classes of capital—ICT ($c_i$) and non-ICT capital ($n_i$)

• The change in employment share of some industry $i$ within a country ($\Delta l_i$)

In addition, we collect data on two measures of skill intensity in the initial year 1983: wage bill shares of skilled labor ($s$) and employment shares of skilled labor ($e$).

The predicted contributions of each capital type to change in the economy-wide skill intensity in production through industry growth alone are

\[
C = \sum_i c_i \Delta l_i s_i \\
N = \sum_i n_i \Delta l_i s_i ,
\]

for ICT and non-ICT capital, respectively. This calculation does not take into account the effect of changes in capital stocks on skill intensity by virtue of uneven complementarities, which is the focus of this paper. The assumption that underpins the validity of these calculations are constant returns to scale industries, since we are using contributions to value added growth $c_i$ and $n_i$ for employment growth. This assumption is not difficult to admit.

We divide $C$ and $N$ by aggregate skill intensity in the initial year, multiply by 100 and divide by the number of years over which they are computed—this gives us annualized percent point contributions to changes in skill intensity through this channel. We compute these both using $s$ and using $e$. The levels tell us how important this channel is. Comparing $C$ to $N$ tells us which type of capital contributed to economy skill intensity more, via changes in production patterns. The results are summarized in Table A2.

We find that—through this specific channel—the contributions of ICT and non-ICT to increases in skill intensities are small. We also find that non-ICT capital contributes just as much to increases in skill intensity, if not more.

**E Exogeneity of instruments**

Denote log values in lower case. Then (5) becomes

\[
m_{oit} = \alpha_{it} + \delta_{it} dist_{oi} + \varepsilon_{oit} .
\]

Here $dist_{oi}$ may be exogenous, but the OLS estimator of $\delta_{it}$ may be biased. The exogeneity of the predicted values of this regression may be violated if the OLS estimator of $\delta_{it}$ varies systematically with omitted variables in (4), or with $\Delta \omega_{it}$ directly.

Suppose that there is an omitted variable in (13). Rewrite (13) as

\[
m_{oit} = \alpha_{it} + \delta_{it} dist_{oi} + u_{oit} + \gamma x_{oit} ,
\]

where $u$ is an orthogonal error and $x$ is an omitted variable, possibly correlated with $dist$. Fix $i$ and $t$. The OLS estimator of $\delta_{it}$ in (13) is

\[
\hat{\delta}_{it} = \delta_{it} + \gamma \frac{\sum \alpha (dist_{oi} - \bar{dist}_i) (x_{oit} - \bar{x}_it)}{\sum \alpha (dist_{oi} - \bar{dist}_i)^2} + \frac{\sum \alpha (dist_{oi} - \bar{dist}_i) u_{oit}}{\sum \alpha (dist_{oi} - \bar{dist}_i)^2} ,
\]
and the probability limit is

$$\text{Plim} \hat{\delta}_{it} = \delta_{it} + \gamma \frac{\text{cov}(\text{dist}_{oi}, x_{oit}|i, t)}{\text{var}(\text{dist}_{oi}|i)} . \quad (16)$$

We could also have $\gamma$ vary along $i$ and $t$, but this is sufficient to illustrate the potential for bias. Recall that we use $\hat{\delta}_{it} \text{dist}_{oi}$ to construct the instruments. If the second term in (16) varies systematically by $i$ and $t$ in a way that is correlated with omitted variables in (4), or with $\Delta \omega_{it}$ directly, then we may have concerns for exogeneity of the instruments. Note that this requires more than the existence of such a covariance; it means that the covariance between distance and $x$ across origin countries varies systematically over $i$ and $t$. While impossible to prove or disprove, it is difficult to think of omitted variables with such properties.

F Derivation of complementarity equation

Let there be two types of capital, $k_1$ and $k_2$, which are quasi-fixed, and let there be two variable inputs: Skilled and unskilled labor, $h$ and $l$, respectively (what follows extends to additional variable and/or quasi-fixed inputs). In this case, variable costs are given by $c = w_h \cdot h + w_l \cdot l$. If $h$ and $l$ are the argmin of costs, then $c$ is the cost function. The logarithm of $c$ can be approximated by a translog cost function:

$$\ln (c) = \alpha_h \ln (w_h) + \alpha_l \ln (w_l) + \alpha_{k_1} \ln (k_1) + \alpha_{k_2} \ln (k_2) + \alpha_y \ln (y) +$$

$$+ \frac{1}{2} \left[ \beta_{hh} \ln (w_h)^2 + \beta_{hl} \ln (w_h) \ln (w_l) + \beta_{hh} \ln (w_l)^2 + \beta_{hl} \ln (w_h) \ln (w_l) + \beta_{hl} \ln (w_l)^2 \right]$$

$$+ \beta_{k_1 k_1} \ln (k_1)^2 + \beta_{k_1 k_2} \ln (k_2)^2 + \beta_{k_2 k_2} \ln (k_2)^2 + \beta_{y y} \ln (y)^2$$

$$+ \gamma_{h k_1} \ln (w_h) \ln (k_1) + \gamma_{h k_2} \ln (w_h) \ln (k_2) + \gamma_{h y} \ln (w_h) \ln (y)$$

$$+ \gamma_{l k_1} \ln (w_l) \ln (k_1) + \gamma_{l k_2} \ln (w_l) \ln (k_2) + \gamma_{l y} \ln (w_l) \ln (y)$$

$$+ \gamma_{k_1 k_1} \ln (k_1)^2 + \gamma_{k_1 k_2} \ln (k_1) \ln (k_2) + \gamma_{k_1 y} \ln (k_1) \ln (y) + \gamma_{k_2 y} \ln (k_2) \ln (y) ,$$

where $y$ is output. Symmetry implies $\beta_{hl} = \beta_{lh}$.

By Shephard’s lemma, $\partial c / \partial w_h = h$, so that the cost share of skilled labor is

$$S \equiv \frac{w_h h}{c} = \frac{\partial \ln (c)}{\partial \ln (w_h)} = \frac{\partial c}{\partial w_h} \frac{w_h}{c} .$$

Using this in the translog we get

$$S = \alpha_h + \beta_{hh} \ln (w_h) + \beta_{hl} \ln (w_l) + \gamma_{h k_1} \ln (k_1) + \gamma_{h k_2} \ln (k_2) + \gamma_{h y} \ln (y) .$$

By linear homogeneity of cost with respect to prices, cost shares are homogenous of degree zero; therefore $\beta_{hh} + \beta_{hl} = 0$. By linear homogeneity of the production function we have $\gamma_{h k_1} + \gamma_{h k_2} + \gamma_{h y} = 0$ (increasing all inputs by same factor increases output by same factor, but this should not affect the cost share). Using these two properties gives

$$S = \alpha + \beta \ln \left( \frac{w_h}{w_l} \right) + \gamma_{k_1} \ln \left( \frac{k_1}{y} \right) + \gamma_{k_2} \ln \left( \frac{k_2}{y} \right) ,$$

which is used in the main text.
G  Trade liberalization and changes in the composition of capital imports: FOB sample

We now address the few cases where tariffs are applied to FOB (free on board) prices, exclusive of freight costs. Denote the countries for which this rule applies as the "FOB sample": Afghanistan, Australia, Botswana, Canada, Democratic Republic of the Congo, Lesotho, Namibia, New Zealand, Puerto Rico, South Africa, Swaziland, and the United States. See http://export.customsinfo.com/ and http://export.gov/logistics/eg_main_018142.asp. We thank Robert Feenstra for this reference.

In those cases, (8) becomes

\[ \frac{r_C}{r_K} = \frac{r_C^* (1 + \tau_C) + f_C + b_C}{r_K^* (1 + \tau_K) + f_K + b_K} = \frac{r_C^*}{r_K^*} \cdot \frac{1 + \tau_C + f_C + b_C}{1 + \tau_K + f_K + b_K}, \]  

(17)

where \( b_j \equiv \frac{\tilde{b}_j}{r_j^*} \) is the ad valorem equivalent distance related cost, and \( f_j \) is defined above. Our findings above pertain to this case as well, but we can say something more here. If tariffs, transportation and distance-related costs are lower for R&D-intensive capital imports, then a blanket drop in tariffs at the same rate will also reduce \( r_C/r_K \). To see this, write (17) as

\[ \frac{r_C}{r_K} \bigg|_{\Delta \tau = 0} = \frac{r_C^*}{r_K^*} \cdot \frac{(\tau_K + f_K + b_K) - (\tau_C + f_C + b_C)}{(1 + \tau_K + f_K + b_K)^2}. \]

This derivative is positive if \((\tau_K + f_K + b_K) > (\tau_C + f_C + b_C)\). Contemplating an equal percent point drop in tariffs for both \( K \) and \( C \) is meaningful if the absolute difference between them before liberalization is not too large—which is what we observe. This is consistent with a larger drop in percent terms in \( 1 + \tau_C \) versus \( 1 + \tau_K \) found above, since we find \( \tau_C < \tau_K \). We now show that this is indeed the case. As above, we keep the exposition of results to a minimum; full statistical outputs are available upon request.

First, we estimate that \( \tau_C \) is smaller than \( \tau_K \) in the FOB sample. Using the same TRAINS tariff data and definitions above, we fit fixed effects regressions

\[ \tau^j_H = \beta I (j \in M_H) + \alpha_i + \delta_t + \varepsilon_H, \]  

(18)

where \( \alpha_i \) is a country fixed effect and \( \delta_t \) is a year fixed effect. We cluster standard errors by country. We estimate \( \beta = -1.77\% \) and highly statistically significant. If we only consider the first year in the sample for each country (i.e. \( t = 1 \)), then we find \( \beta = -2.6\% \).

Second, we estimate that freight costs are lower for R&D-intensive capital transported via sea, but the opposite is true for shipments via air. Sea shipments are the bulk of shipment value in the U.S. import data, 64% on average throughout the period. Using the same ad-valorem freight data used above to estimate (10), we fit regressions of the type

\[ f_j = \beta I (j \in M_H) + \gamma \ln (u/v)_j + \alpha_{s(j)} + \delta_{t(j)} + \varepsilon_j, \]  

(19)

where \( \alpha_{s(j)} \) is a source \( s \) fixed effect for all shipments \( j \) imported from source \( s \), and \( \delta_{t(j)} \) is a
time fixed effect for all shipments $j$ that are observed in year $t$ (which absorbs global changes in fuel prices). In the estimation we weigh observations by shipment value and cluster standard errors by source country. When we estimate (19) for sea shipment we also control for the share of containerized trade in the shipment. We estimate, with high precision, that $\beta = -0.33$ percent points for sea shipments, but $+0.23$ percent points for air shipments. When we do not weigh observations by value, we estimate, with high precision, that $\beta = -1.27$ percent points for sea shipments and $-2.1$ percent points for air shipments.

Finally, we estimate that bilateral barriers to trade are lower for $M_H$ relative to $M_L$. We estimate the following gravity equations separately for each year in 1984–1999 (which is the most appropriate way to do this; see Head and Mayer (2014)):

$$m^j_{si} = \beta \cdot I(m^j_{si} \in M_H) + \chi_s + \eta_i + \epsilon^j_{si},$$

where $m^j_{si}$ are log capital imports from source $s$ to importer $i$ of capital type $j \in \{M_L, M_H\}$; and $I(m^j_{si} \in M_H)$ indicates whether $m^j_{si}$ is of type $M_H$ ($= 1$) or not ($= 0$). Exporter and importer fixed effects—$\chi_s$ and $\eta_i$—respectively, capture demand conditions in the importer countries and technology in the source country. It is important to see that the latter ensure that $\beta$ is identified only by bilateral variation in barriers to trade for $M_H$. This coefficient absorbs the differential effect of all bilateral trade impediments (inter alia, distance, language, colonial ties, tariffs, freight costs, etc.).

We estimate this equation by OLS, clustering standard errors by country-pair, using import data in 1984–1999, both for 157 countries (136,786 observations) and for the twelve countries in the FOB sample (12,786 observations). In both samples and in every year we find that $\beta < 0$; on average across years $\beta = -0.179$ for the entire sample, and for the FOB sample $\beta = -0.164$ on average, which indicates that bilateral trade resistance falls for $M_H$ is lower than $M_L$ on average.

When also we estimate the gravity equation with a Heckman correction for sample selection along the lines of Helpman, Melitz, and Rubinstein (2008), using their common religion index as an excluded variable in the selection equation. This increases the magnitude of the coefficients to $I(m^j_{si} \in M_H)$, but hardly affects their trend over time. To summarize, bilateral barriers to trade are lower for $M_H$ relative to $M_L$, regardless of how we estimate this.
References

Figure 1: Wage Inequality and the Composition of Capital Imports, 1983-2000

Notes to Figure 1: The figure displays the partial correlation between changes in log skilled relative wage, defined as the wage of non-production workers to production workers, and the capital import ratio, defined as the ratio of R&D-intensive capital equipment imports relative to less innovative capital equipment imports. We control for the change in skill abundance, country and period fixed effects, total capital imports divided by GDP, and shifts in the skill intensity of export shares; as in Table 6, column 3, the slope is 0.04 and the partial $R^2$ is 0.11.

Notes: R&D intensity rank by ISIC, rev.2 (numbers in parentheses) in 1980 is from Caselli and Wilson (2004). This ranking is based on their estimates of world R&D expenditures divided by world sales for each capital good; it is the same whether R&D flows or stocks (perpetual inventory method) are used. See appendix for more detailed descriptions of ISIC capital classifications. We allocate EU-KLEMS ICT classifications to the ISIC classification based on the EU-KLEMS documentation. See O’Mahony and Timmer (2009) for documentation of the EU-KLEMS database. The degree of complementarity with skilled or unskilled labor is from authors' baseline estimation.

Notes: The sample includes 63 observations, covering 21 developing countries over the period of 1983-2000. Δln(wH/wL) is the change in the logarithm of skilled relative wage in manufacturing; Δln(H/L) is change in logarithm of aggregate relative supply of skill; Δz is shift in export shares to high income OECD countries; ln(import ratio) is the logarithm of the ratio of R&D-intensive capital imports to R&D-unintensive capital imports; ln(capital imports/GDP) is the logarithm of capital imports (for the R&D-intensive, unintensive, and the overall aggregated group) normalized by GDP; Δln(FDI) is the change in the logarithm of the average US FDI (2005 prices). Δln(GDP/POP) is the change in the logarithm of GDP per capita. ΔIndustrial, ΔGovernment, ΔServices share are the changes in the logarithm of the sectoral value added shares in GDP. ΔFinancial-development is the change in the logarithm of M3 money supply as a fraction of GDP. ΔIPR-protection is the change in the Intellectual Property Rights Protection Index from Ginarte and Park (1997), updated by Park (2008). IPR-protection data are available every 5 years, so we linearly interpolate between observations within a country. Δln(K) is change in the logarithm of total real capital stock (Penn World Tables, mark 8.0); capital stock data is not available for Algeria. lnMHML_gravity, lnMHgdp_gravity, lnMLgdp_gravity, and lnMgdp_gravity are the import ratio, R&D-intensive, R&D-unintensive, and aggregate imports instruments, respectively. All variables in levels are averages within change periods, while all variables in changes are annual changes. For further details on countries in the sample, data construction and sources, see Appendix.

Notes: In Panel A import capital shares are computed as shares in total capital imports and averaged over the sample used for the regressions in Tables 5-8. Country samples are noted next to each country. In Panel B average annual changes in capital import shares are computed as the share in the last year minus the share in the first year divided by the number of years for each country. Averages over all countries are reported below country data. Import data are from Feenstra et al. (2005).

</table>

Notes: This table reports average shares of imports and net imports (= imports - exports) in implied investment for two types of capital goods and for their sum, where implied investment = output + imports - exports. Capital types are: H = high R&D intensity (ranks 1, 2, 3, 4, 6), skill-complementary; L = low R&D intensity (ranks 5, 7, 8, 9), unskilled-complementary; ALL = H + L. Import data correspond to this classification exactly; output data do not distinguish aircraft equipment from other transportation equipment, which are included in group L. Output data are from UNIDO and trade data are from Feenstra et al. (2005). The sample is the same as in the inequality regressions, but due to UNIDO data limitations the sample is not full for all countries; in particular, there are no output data for Algeria.

Notes: This table reports pairwise correlation coefficients between implied investment and imports of capital goods or net imports of capital goods for two types of capital goods and for their sum. Implied investment = output + imports - exports. Net imports = imports - exports. Capital types are: H = high R&D intensity (ranks 1, 2, 3, 4, 6), skill-complementary; L = low R&D intensity (ranks 5, 7, 8, 9), unskilled-complementary; ALL = H + L. Import data correspond to this classification exactly; output data do not distinguish aircraft equipment from other transportation equipment, which are included in group L. Output data are from UNIDO and trade data are from Feenstra et al. (2005). The sample is the same as in the inequality regressions, but due to UNIDO data limitations the sample is not full for all countries; in particular, there are no output data for Algeria.

**Instrument strength statistics:**
- Shea's partial R-squared: 0.88, 0.27, 0.3, 0.27
- Partial R-squared: 0.98, 0.3, 0.44, 0.39
- F-statistic: 573.26, 8.3, 18.55, 8.01

Notes: All specifications include country and period fixed effects. Standard errors clustered by country in parentheses. *** p<0.01, ** p<0.05, * p<0.1. The dependent variable is Δln(wH/wL), change in the logarithm of skilled relative wage. Main explanatory variables: Δln(H/L) is the change in logarithm of relative supply of skill; ln(MH/ML) is the logarithm of the ratio of R&D-intensive capital imports to R&D-unintensive capital imports; ln(M/GDP) is the logarithm of aggregate capital imports divided by GDP, and similarly for MH, and ML. Δz is shift in export shares as in Zhu and Trefler (2005). lnMHML_gravity, lnMHgdp_gravity, lnMLgdp_gravity, and lnMgdp_gravity are the import ratio, R&D-intensive, R&D-unintensive, and aggregate imports instruments, respectively. All variables in levels are averages within periods, while all variables in changes are annual changes. See appendix for further details on countries in the sample, data construction and sources.

Notes: OLS estimates. All specifications include country and period fixed effects. Standard errors clustered by country in parentheses. *** p<0.01, ** p<0.05, * p<0.1. The dependent variable is Δln(wH/wL), change in the logarithm of skilled relative wage. Main explanatory variables: Δln(H/L) is the change in logarithm of relative supply of skill; ln(MH/ML) is the logarithm of the ratio of R&D-intensive capital imports to R&D-unintensive capital imports; ln(M/GDP) is the logarithm of aggregate capital imports divided by GDP. Δz is shift in export shares as in Zhu and Trefler (2005). In(FDI) is the logarithm of the average US FDI (2005 prices). ln(GDP/POP) is the logarithm of real GDP per capita; industrial, government and services shares are the sectoral value added shares in GDP (all in logarithms); ln(financial development) is the logarithm of M3 money supply divided by GDP; the IPR protection index is the Intellectual Property Rights Protection Index from Ginarte and Park (1997), updated by Park (2008). IPR-protection data are available every 5 years, so we linearly interpolate between observations within a country. ln(K) is the logarithm of total real capital stock (Penn World Tables, mark 8.0); capital stock data is not available for Algeria. All variables in levels are averages within periods, while all variables in changes are annual changes. See appendix for further details on countries in the sample, data construction and sources.

Notes: OLS estimates. All specifications include country and period fixed effects. Standard errors clustered by country in parentheses. *** p<0.01, ** p<0.05, * p<0.1. The dependent variable is Δln(wH/wL), change in the logarithm of skilled relative wage. Main explanatory variables: Δln(H/L) is the change in logarithm of relative supply of skill; ln(MH/ML) is the logarithm of the ratio of R&D-intensive capital imports to R&D-unintensive capital imports; ln(M/GDP) is the logarithm of aggregate capital imports divided by GDP, and similarly for MH, and ML. Δz is shift in import shares as in Zhu and Trefler (2005). In Regressions 1 and 2 we add interactions with a dummy variable IKMP that indicates any of the significant exporters of capital in our sample of developing countries: India, Korea, Mexico, and Philippines. In Regressions 3 and 4 we exclude capital imports from the following six major, high-income producers: France, Germany, Italy, Japan, United Kingdom, and the United States. In Regressions 5 and 6 we separate imports from the six major, high-income, producers from all the rest. All variables in levels are averages within periods, while all variables in changes are annual changes. See appendix for further details on countries in the sample, data construction and sources.

**Notes:** This table reports TSLS estimates of $\gamma_1$ in the regression $S = \beta^*\ln(wH/wL) + \gamma_1^*\log(\text{capital}_{-j}/\text{output}) + \gamma_2^*\log(\text{capital}_{-j}/\text{output}) + \epsilon$, for different capital types $j$, where $\text{capital}_{-j}$ is total capital stock net of $\text{capital}_{-j}$. $S$ is the wage bill share of skilled workers and $wH/wL$ is the relative wage of skilled to unskilled workers. Positive coefficients indicate complementarity to skilled workers; negative coefficients indicate complementarity to unskilled workers. Instruments to capital shares are their 1-period lagged values; all first stage results report F-statistics for weak instruments an order of magnitude greater than 10. All regressions include time and country fixed effects. Data: EU KLEMS. Standard errors in parentheses are clustered at the country level. *** p<0.01, ** p<0.05, * p<0.1.

</tbody>
</table>

Notes: The sample includes 63 observations, covering 21 developing countries over the period of 1983-2000. Δln(wH/wL) is the change in the logarithm of skilled relative wage in manufacturing; Δln(H/L) is change in logarithm of aggregate relative supply of skill; ΔΔ is shift in export shares to high income OECD countries; ln(import ratio) is the logarithm of the ratio of R&D-intensive capital imports to R&D-unintensive capital imports; ln(capital imports/GDP) is the logarithm of capital imports for the R&D-intensive, unintensive, and the overall aggregated group normalized by GDP; Δln(FDI) is the change in logarithm of the average US FDI (2005 prices); Δln(GDP/POP) is the change in the logarithm of GDP per capita; Δln(industrial share) Δln(government share) and Δln(services share) are the changes in the logarithm of the sectoral value added shares in GDP. Δfinancial development is the change in the logarithm of M3 money supply as a fraction of GDP. ΔPR protection is the change in the Intellectual Property Rights Protection Index from Ginarte and Park (1997), updated by Park (2008). ΔPR protection data are available every 5 years, so we linearly interpolate between observations within a country. ΔΔln(K) is change in the logarithm of total capital stock (Penn World Tables, mark 8.0); capital stock data is not available for Algeria. ΔΔlnMHML_gravity, ΔΔlnMHdp_gravity, and ΔΔlnM_gravity are the import ratio, R&D-intensive, R&D-unintensive, and aggregate imports instruments, respectively. All variables in levels are averages within change periods, while all variables in changes are annual changes. For further details on countries in the sample, data construction and sources, see appendix.

Notes: All specifications include country and period fixed effects. Standard errors clustered by country in parentheses. *** p<0.01, ** p<0.05, * p<0.1. The dependent variable is Δln(wH/wL), change in the logarithm of skilled relative wage. Main explanatory variables: Δln(H/L) is the change in logarithm of relative supply of skill; ln(MH/ML) is the logarithm of the ratio of R&D-intensive capital imports to R&D-unintensive capital imports; ln(M) is the logarithm of aggregate capital imports, and similarly for MH, and ML; division by POP means normalization by population, division by K means normalization by total capital stock (Penn World Tables, mark 8.0). In the latter case data is not available for Algeria. Δz is shift in export shares as in Zhu and Trefler (2005). All variables in levels are averages within periods, while all variables in changes are annual changes. See appendix for further details on countries in the sample, data construction and sources.

Notes: In Panel A capital stock shares are computed as shares in total nominal capital stock and averaged over all available years. In Panel B changes in capital stock shares are computed as the share in the last year minus the share in the first year. Samples are noted next to each country. Averages over all countries are reported below country data. Data is from the EU KLEMS dataset (O’Mahony and Timmer, 2009).

Notes: This table reports TSLS estimates of \( \gamma 1 \) in the regression \( \Delta S = \beta \Delta \ln(wH/wL) + \gamma 1 \Delta \log(\text{capital}_i/\text{output}) + \gamma 2 \Delta \log(\text{capital}_-i/\text{output}) + \Delta \epsilon \), for different capital types \( i \), where \( \text{capital}_-i \) is total capital net of capital \( i \). \( S \) is the wage bill share of skilled workers and \( wH/wL \) is the relative wage of skilled to unskilled workers. \( \Delta \) is the first difference operator. Positive coefficients indicate complementarity to skilled workers; negative coefficients indicate complementarity to unskilled workers. Instruments for capital shares are their 1-period lagged values (both in changes); all first stage results report F-statistics higher than 1000. All regressions include country fixed effects. Data: EU KLEMS. Standard errors in parentheses are clustered at the country level. *** \( p<0.01 \), ** \( p<0.05 \), * \( p<0.1 \).

Notes: In Panel A capital stock shares are computed as shares in total nominal capital stock and averaged over all available years. In Panel B changes in capital stock shares are computed as the share in the last year minus the share in the first year. Samples are noted next to each country. Averages over all countries are reported below country data. Capital stock data was aggregated according to the classification in Table 1 based on data from OECD. Stocks are calculated by perpetual inventory method, using capital type-specific depreciation. Investment of each capital type is given by I = Y - X + M, where Y is output, X are exports and M are imports (data from OECD). See main text for complete details.
